

## Lecture 13

Lecturer: Dan Spielman

Scribe: Abhinav Kumar

This lecture will be on oracle quantum turing machines.  
 We wish to compare Quantum complexity classes to ordinary complexity classes.

**Fact 1**  $BQP \subseteq PSPACE$ 

This is easy to prove, in fact it's on the problem set. A harder proposition is the following.

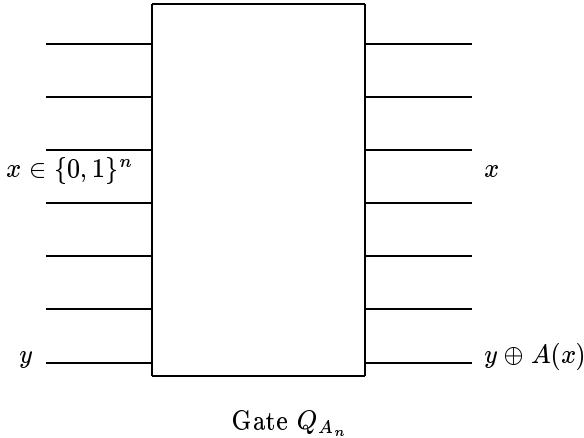

**Fact 2**  $BQP \subseteq P^{\#P}$ 

Another result says

$$\exists A \text{ such that } NP^A \notin BQP^A.$$

So at least in its ability to access an oracle, NP can be more powerful than BQP.

We need to define the notion of accessing an oracle for a quantum computer. The idea is to put quantum gates in the circuit representing the oracle. An oracle is viewed as a function  $A : \{0,1\}^n \rightarrow \{0,1\}$ . We consider the quantum gate  $Q_{A_n}$ , as shown in the figure.

To describe the quantum gate  $Q_A$ , assume that  $A$  tells us what  $Q_A$  does on basis states  $|x,y\rangle$ ,  $x \in \{0,1\}^n$ ,  $y \in \{0,1\}$ .  $Q_A$  sends this to  $|x,A(x) \oplus y\rangle$ . Extend by linearity to get a unitary transformation.

Then an oracle quantum turing machine just means a quantum circuit which is allowed to incorporate some gates of this form.

Let  $L(A) = \{w \mid \exists x \in A, |x| = |w|\}$ . Clearly  $L(A) \in NP^A$ . We will see that quantum computers can't decide  $L(A)$  very well. Putting in one word of a given length makes very slight difference to the functioning of a quantum circuit trying to decide  $L(A)$ . The rough idea is that if  $|A \cap \{0,1\}^n| = 0$  or 1, it doesn't make much of a difference which of these values it is (to a Quantum circuit). The proof idea is similar to the proof of  $P^A \subsetneq NP^A$ .

**Theorem 3**  $L(A) \notin BQP^A$

**Proof:** Suffices to argue about one quantum circuit. The way we elude all Quantum circuits is the same as in the proof of  $P^A \subsetneq NP^A$ . In fact, if a quantum circuit with  $T$  oracle gates accepts  $L(A)$  with error probability less than a fixed constant, then  $T = \Omega(2^{n/2})$  (this bound is tight - see Grover's algorithm). Define Let the initial state be  $|\phi_0\rangle$ .

$$|\phi_T\rangle := U_T Q_A \dots Q_A U_1 |\phi_0\rangle$$

where  $U_i$ 's are unitary matrices,  $T$  refers to time steps for the circuit. the language  $A$  acts as an oracle: if  $x \in \{0, 1\}^n$ , then  $A(x) = 0$  if  $x \in A$ , 1 if  $x \notin A$ . Note that if  $|A \cap \{0, 1\}^n| = 0$ , then  $Q_{A_n}$ , is the identity. We will compare two cases: no words against exactly one word. Define

$$|\theta_i\rangle := U_i \dots U_1 |\phi_0\rangle$$

Our goal is to find  $x \in \{0, 1\}^n$  such that if  $A_n = \{x\}$ , then  $\|\phi_T - \theta_T\| > \text{const.} \Rightarrow T$  is huge.

**Lemma 4**  $\exists x \in \{0, 1\}^n$  such that  $\|\phi_T - \theta_T\| \leq \sqrt{\frac{2T^2}{2^n}}$

Before we prove the lemma, we state a corollary:

**Claim:** If  $T = o(2^{n/2})$  then this circuit can't distinguish between  $|A \cap \{0, 1\}^n| = 0$  or 1.

Now our goal is to find  $x$  so that it's not queried in a meaningful way. Assume w.l.o.g. that there is a distinguished set of wires that are inputs to the  $Q_A$  gate, i.e. assume dedicated input wires for  $Q_A$ . For a state

$$|\psi\rangle = \sum_{c \text{ basis state}} \alpha_c |c\rangle$$

we define the query magnitude of  $x$  in  $\psi$  to be  $\sum_{c \in S_x} |\alpha_c|^2$ , where

$$S_x = \{ \text{basis states with } x \text{ on oracle wires} \}$$

**Def.** The query magnitude of  $x$  at time  $i$  is  $q_{i,x} =$  the query magnitude of  $x$  in  $\theta_i$ .

**Def.** The query magnitude of  $x$ ,  $q_x = \sum_{i=1}^T q_{i,x}$ .

Idea: take  $x$  of minimal query magnitude so  $q_x < \frac{T}{2^n}$ , because  $\sum_x q_{i,x} = 1$  for every  $i$ .

**Claim:**  $\|\theta_T - \phi_T\| \leq \sqrt{T \cdot 2q_x}$  (this  $\Rightarrow$  Lemma 4).

**Proof of claim:**

Let  $V_i = U_i Q_A$ .

$$\begin{aligned} |\phi_T\rangle &= (V_T V_{T-1} \dots V_1) |\phi_0\rangle \\ |\theta_T\rangle &= (U_T U_{T-1} \dots U_1) |\phi_0\rangle \\ \psi_{k,i} &= V_i V_{i-1} \dots V_{k+1} U_k \dots U_1 |\phi_0\rangle \quad (\text{called the k'th hybrid at time i}) \\ \text{so } \psi_{0,T} &= V_T \dots V_1 |\phi_0\rangle \\ \psi_{k,T} &= V_T \dots V_{k+1} U_k \dots U_1 |\phi_0\rangle \\ \psi_{T,T} &= U_T \dots U_1 |\phi_0\rangle \end{aligned}$$

Compare  $\psi_{k,k+1}$  with  $\psi_{k+1,k+1}$ .  
 $\theta_k = \psi_{k,k}$ , we apply either  $V_k$  or  $U_k$ . It is easily verified that

$$\|\psi_{k,k+1} - \psi_{k+1,k+1}\| \leq 2q_{k,x}$$

$$\Rightarrow \|\psi_{k,k+1} - \psi_{k+1,k+1}\|^2 \leq 2q_{k,x} \text{ since } \|\psi_{k,T} - \psi_{k+1,T}\|^2 = \|\psi_{k,k+1} - \psi_{k+1,k+1}\|^2$$

because unitary transformations preserve norms. Therefore

$$\sum_{k=0}^{T-1} \|\psi_{k,T} - \psi_{k+1,T}\|^2 \leq \sum_{k=0}^{T-1} 2q_{k,x} \leq 2q_x$$

By Cauchy-Schwartz,

$$\|\theta_T - \phi_T\| = \|\psi_{0,T} - \psi_{T,T}\| \leq \sum_k \|\psi_{k,T} - \psi_{k+1,T}\| \leq \sqrt{2q_x T}$$

### Grover's Algorithm

Search in  $O(\sqrt{N})$  time. Let  $H$  be the Hadamard matrix

$$M = \frac{1}{\sqrt{2}} \begin{bmatrix} 1 & 1 \\ 1 & -1 \end{bmatrix}$$

Also, let us consider the matrix corresponding to the gate  $NOT$ ,

$$Q_{NOT_2} = \begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix}$$

We shall use the matrices  $H$  and  $NOT$  to get a unitary transformation that flips the sign of one bit, namely  $U = H \cdot NOT \cdot H$ .

$$U = \frac{1}{2} \begin{bmatrix} 1 & 1 \\ 1 & -1 \end{bmatrix} \cdot \begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix} \cdot \begin{bmatrix} 1 & 1 \\ 1 & -1 \end{bmatrix} = \begin{bmatrix} 1 & 0 \\ 0 & -1 \end{bmatrix}$$

Using this machinery, we can construct a gate  $Q'_A$  for an oracle  $A$ , which takes  $|x> to -|x>$  if  $x \in A$ , and leaves  $|x>$  unchanged otherwise (note this is a unitary transformation, since it is unitary on the orthogonal basis vectors, and takes them to orthogonal vectors).

So if  $A = 01$ ,  $Q'_A|01> = -|01>$ . Suppose we apply this transform to a uniform linear combination of states

$$|x_0> = \frac{1}{2}(|00> + |01> + |10> + |11>)$$

We get out

$$\frac{1}{2}(|00> - |01> + |10> + |11>)$$

Now suppose to the result we apply a Hadamard transform to each bit, then apply the matrix

$$\begin{bmatrix} 1 & & & \\ & -1 & & \\ & & -1 & \\ & & & -1 \end{bmatrix} \text{ (reflection about mean)}$$

to it, and again the Hadamard transform to it. We get out just  $|01>$ !

The Hadamard transform acts as a Fourier transform. The general algorithm is based on these lines, the idea is to iterate, applying these two gates (the diffusion transform and  $Q'_A$ ), when we have more than 2 inputs.

$$RQ'_A RQ'_A \dots |x_0> (\frac{4}{\pi} \sqrt{2^n} \text{ times})$$

the dominant term will be the word we want to select. This takes time  $O(\sqrt{N})$  since  $N \approx 2^n$ .
